ABSTRACT

The brown planthopper (BPH), *Nilaparvata lugens* can cause direct damage and transmit rice diseases. *Beauveria bassiana* is used to control BPH, however the success of the fungal efficacy on rice fields is affected by external factors, such as temperature. This research aimed to evaluate the conidial viability and density of *B. bassiana* isolates from Java and Sumatra, exposed to 25 and 34°C and their virulence against BPH nymphs. Twenty six isolates of *B. bassiana* cultures incubated at 25 and 34°C for 7 days were observed on their conidial density, viability, and virulence against BPH nymphs. The incubation temperature of 34°C was able to decrease conidial density and viability, and virulence of the isolates. However, some isolates of *B. bassiana* originated from soils or insects in Sumatra, especially from South Sumatra still produced high conidial density and viability as well as high virulent against BPH nymphs, such as TS1D3A, TS1D3B, TS1D2A and TS1D2B isolates. The TS1D2B isolate incubated at 34°C still caused the highest percentage of BPH mortality (43.33%) among other isolates. Therefore, the isolates can be used as promising candidate for biocontrol for *N. lugens* on rice planted in tropical ecosystem, such as wetland or lowland rice ecosystems in Indonesia.

INTRODUCTION

The brown planthopper (BPH), *Nilaparvata lugens* Stal. (Hemiptera: Delphacidae) is the most serious insect pest which sucks phloem sap on stems of rice (*Oryza sativa* L.) (Daravath & Chander, 2017; Herlinda et al., 2018). A direct damage caused by this BPH results in hampered growth of rice producing 'hopperburn' (Dharshini & Siddegowda, 2015). In addition, BPH can also as an insect vector that transmits rice diseases, such as the ragged stunt and grassy stunt virus (Dietzgen, Mann, & Johnson, 2016; Zheng, Mao, Xie, & Wei, 2014). The attack of BPH do not only occur in Indonesia, but also attack rice in several Asian countries, such as China, Vietnam, Thailand,

India, Pakistan, Malaysia and Philippine (Catiding et al., 2009; Hu et al., 2014). BPH also attacked rice in Texas (Leavengood, Bartlett, & Vitanza-Hedman, 2017).

The effort to control population of *N. lugens* had been done through synthetic chemical control (Baehaki & Suparno, 2018; Liu et al., 2013; Zhang et al., 2014) and biological control by using entomopathogenic fungi, such as *Beauveria bassiana* (Lee et al., 2015; Li, Lin, Li, Xu, & Feng, 2012) and *Metarhizium anisopliae* (Chinniah, Ravikumar, Kalyanasundaram, & Parthiban, 2016) have been proven to be effective agents to control the BPH. *B. bassiana* could kill BPH more than 80% (Lee et al., 2015; Li et al., 2014) and to kill the eggs

Conidial Density and Viability of *Beauveria bassiana* Isolates from Java and Sumatra and Their Virulence Against *Nilaparvata lugens* at Different Temperatures. *AGRIVITA Journal of Agricultural Science*, 41(2), 335–350. <http://doi.org/10.17503/agrivita.v41i2.2105>

of BPH as well as to disturb adult stage proliferation (Li, Lin, Li, Xu, & Feng, 2012). *B. bassiana* is also not harmful toward natural enemies of the BPH (Firouzbakht, Zibae, Hoda, & Sohani, 2015; Gholamzadeh-Chitgar, Hajizadeh, Ghadamyari, Karimi-Malati, & Hoda, 2017).

Although *B. bassiana* had proven to be effective in controlling the BPH, the success of its efficacy on rice fields was affected by many external factors, such as temperature (Ghany, 2015). Extremely high temperature results in death of the fungus (Ottati-de-Lima et al., 2014). The optimum temperature for growth of the entomopathogenic fungi usually is in the range of 25 to 30 °C (Bugeme, Maniania, Knapp, & Boga, 2008). Most of entomopathogenic fungi tolerate to temperatures in the range of 0 to 40 °C (Ghany, 2015), but certain strains of entomopathogenic fungi can only survive at temperatures below 35 °C (Constanski et al., 2011). The production of colony and conidial density of *B. bassiana* is significantly decreased if temperature during fungal incubation increases from 30 to 35 °C (Ottati-de-Lima et al., 2014) and all isolates are dead at temperature of 36 °C (Ottati-de-Lima et al., 2014; Pham, Kim, Kim, & Kim, 2009). Fungal germination is also decrease at temperature above 30 °C (Pham, Kim, Kim, & Kim, 2009) with the highest level up to 33 °C (Salim, Md. Rawi, Ahmad, & Al-Shami, 2015), whereas temperature of 25 °C is an ideal temperature for the fungal germination (Lohse, Jakobs-Schönwandt, & Patel, 2014). Virulence of the entomopathogenic fungi can be affected by temperature (Bugeme, Maniania, Knapp, & Boga, 2008; Constanski et al., 2011; Ghany, 2015; Ottati-de-Lima et al., 2014; Satpathi, Acharjee, & Saha, 2016; Tefera & Pringle, 2003). Each strain/isolate or species of the entomopathogenic fungi also has different optimum temperature and tolerance level to temperature. Entomopathogenic fungal strains that can survive at extremely high temperature of above 33 °C are superior strains (Salim, Md. Rawi, Ahmad, & Al-Shami, 2015). These superior strains can be used as candidates to control the BPH in tropical ecosystems, such as agroecosystems in Indonesia. Therefore, the objectives of this research were to evaluate the conidial viability and density of *B. bassiana* isolates from Java and Sumatra exposed to 25 and 34 °C temperatures and their virulence against *N. lugens* nymphs.

MATERIALS AND METHODS

Study Site

This research was conducted at Laboratory of Entomology, Department of Plant Pests and Diseases, Faculty of Agriculture, Universitas Sriwijaya, Indralaya, from September 2017 to April 2018. Isolates used in this research were isolates that collected from soil of lowland swamps, tidal lowlands, peatlands, and highlands in South Sumatra, whereas isolates from soil and infected insects obtaining from other provinces used as comparison as well as one commercial isolate as control (Table 1). The species of the fungus was identified by Dr. Suwandi, a microbiologist from Department of Plant Pests and Diseases, Faculty of Agriculture, Universitas Sriwijaya. The average room temperature during the experiment was 30.5 °C and the average relative humidity was 84.30% within the laboratory during the experiment.

Preparation of Test Insects

Adults and nymphs of *N. lugens* were collected from fields of rice at Indralaya, South Sumatra from September 2017 to March 2018 and brought to the Laboratory of Entomology, Department of Plant Pests and Diseases, Faculty of Agriculture, Universitas Sriwijaya, Indralaya for identification. Then, the nymph and adults were reared and maintained on 5 clumps of 10-day-old rice grown within bucket (bottom diameter of 20 cm, upper diameter of 25 cm, and height of 20 cm) within a greenhouse at temperature range of 30 to 35 °C. The rice was put in wire mesh enclosure (height of 100 cm, length of 50 cm, and width of 50 cm). Within one of wire mesh enclosure, 10 pairs of the adults were released in order to infect the rice for 10 days and subsequently the infected rice crops were substituted with the healthy one and this propagation was done on 30 cages. Fresh and healthy rice were given to newly emerged nymphs of *N. lugens* and this was maintained up to at least five generations. The sixth generation and henceforth generations were used and selected for the fourth instar for bioassay in this experiment.

Isolates Preparation of *Beauveria bassiana*

All isolates used in this study were previously fitted by using living insects of *Tenebrio molitor*. Fresh cultures of *B. bassiana* were started by inoculating Sabouraud Dextrose Agar (SDA) (Oxoid) with the third larvae of *T. molitor*. Prior to inoculation, *B.*

Eka Sumikarsih et al.: *Beauveria bassiana* for *Nilaparvata lugens*.....

bassiana and *T. molitor* were previously sterilized by using modified method from Nuraini, Setyaningsih, & Susilowati (2017). Subsequently, the fungal culture was incubated for 7 x 24 hours in order to produce sufficient numbers of fungal colony. The *B. bassiana* culture that had previously fitted was then used for subsequent observation. The fresh *B. bassiana* culture was cut with dimension of 10 mm x 10 mm for recultured into SDA medium which would be used for subsequent observation consisting of conidial density and viability as well as virulence test.

4 Observation of Conidial Density and Viability

Twenty six isolates of the *B. bassiana* culture were grown on SDA medium and then each isolate was incubated at constant temperature of 25 and 34 °C within incubator for 7 x 24 hours using three replications. The ideal temperature of 25 °C and extremely high temperature of 34 °C in this research were chosen for culturing of *B. bassiana* for 7 days. Both temperature were chosen because

the temperature of 25 °C is ideal temperature for culture *B. bassiana* (Bugeme, Maniania, Knapp, & Boga, 2008), whereas temperature higher than 33 °C is extremely high temperature (Salim, Md. Rawi, Ahmad, & Al-Shami, 2015). Conidia of all isolates at the 8th day were counted in term of their density of the 7 day *B. bassiana* culture. Calculation of conidial density was started with fungal suspension production by harvesting 10 mm x 10 mm (1 cm²) 7-day *B. bassiana* culture which followed by 10 ml addition of sterile distilled water. The suspension was vortexed using turbo mixer for 20 seconds in order to produce homogenous conidial suspension. This suspension culture was diluted through addition of 9 ml sterile distilled water into 1 ml *B. bassiana* suspension culture, homogenized. Subsequently, the last suspension culture was counted in term of its conidial density under a compound microscope at 400x magnification that had been equipped with haemocytometer. This treatments were arranged in completely randomized design and replicated three times.

The calculation of conidial viability was based on percentage of conidial germination. The conidial germination was observed from the 7-day *B. bassiana* culture which incubated at 25 or 34 °C and grown on one layer of SDA medium according to the method of Bugeme, Maniania, Knapp, & Boga (2008). The 7-day *B. bassiana* suspensions culture was scratched with magnitude of 0.1 ml on SDA plates. A sterile microscope cover slip was placed on each plate, then each suspension culture was incubated for 24 and 48 hours at temperature of 25 °C. Furthermore, the germinated conidia was observed under microscope and calculation was done in term of numbers of germinated conidia.

The germination percentage was determined from 100-spores for each plate using the compound microscope. These treatments were arranged in completely randomized design and replicated three times.

Bioassay Procedure

Bioassays by modification of Trizelia & Nurdin (2010) method were conducted to determine the virulence of *B. bassiana* isolates against *N. lugens* nymphs. The 26 isolates of *B. bassiana* were incubated at 25 and 34 °C for 7 days and their conidia were harvested. Each isolates of *B. bassiana* was topically sprayed with 10 ml of a concentration

RESULTS AND DISCUSSION

Conidial Density and Viability of *Beauveria bassiana*

B. bassiana culture that was incubated for 7 days at temperature of 25 °C showed the highest conidial density on BTmSo isolate and was not significantly different from that of BPcMs, TS1D3A, TSID3B, TS1D2A and TS1D2B isolates (Table 2). At incubation temperature of 34 °C, the highest value of conidial density was found on TS1D2B isolate and was significantly different than that of BPcPd2 isolate which had the lowest conidial density value. Conidial density of all isolates at 25 °C were significantly higher than the isolates at 34 °C ($P = 0.00$) (Fig. 1). Conidial density significantly decreased with the increase of the fungal incubation temperature and followed by more hampered of fungal colony growth. Fungal culture incubated for 7 days at 25 °C had normal growth with colony diameter in the range of 50 to 90 mm, whereas colony of *B. bassiana* incubated at 34 °C only had diameter in the range of 15 to 30 mm (Fig. 2). Incubation temperature of 34 °C for *B. bassiana* culture was able to decrease conidial density and colony growth of the fungus; however some isolates (TS1D3A, TSID3B, TS1D2A and TS1D2B isolates) still achieved high conidial density and colony growth.

of 1×10^3 conidia per cm^2 on 25 fourth-nymphs of *N. lugens* placed on a filter paper in petri dishes. Then, the nymphs of *N. lugens* were placed into 20 healthy two-weeks rice stems. This treatments were arranged in completely randomized design and replicated three times. Numbers of dead *N. lugens* nymphs was recorded every 12 hours for 11 days period which used to determine the percentage of mortality and lethal time to 50% (LT_{50}) and 95% (LT_{95}) mortality of *N. lugens* nymphs. The behaviour change of *N. lugens* infested by *B. bassiana* was observed and recorded daily until the insects were dead and mycelia cover all of their bodies. The dead nymphs were transferred into petri dishes lined with moist-sterile filter paper to allow the growth of the *B. bassiana* on the surface of the cadaver.

Data Analysis

Data of conidial density and viability and percentage of mortality among treatments were analyzed by using analysis of variance (ANOVA). If there were differences among the data of each isolate, then Honestly Significant Different (HSD) test at 5% was conducted by using program software of SAS University Edition 2.7 9.4 M5. The data between temperature were compared using t test. LT_{50} and LT_{95} values were calculated using probit analysis.

Fig. 1. Conidial density of *Beauveria bassiana* culture incubated for 7 days at 25 and 34 °C ($P = 0.00$)

Fig. 2. Colony growth of *Beauveria bassiana* culture incubated for 7 days at 24 °C (a) and 34 °C (b) (90 mm diameter of petri dish).

Fig. 3. Conidia of *Beauveria bassiana* (a), viable conidia at 24-hour (b) and 48-hours (c) suspension culture of *Beauveria bassiana* (400x magnification)

Conidial density values of *B. bassiana* isolate cultures incubated at 25 °C were all high, but higher values were found on isolates of BtmSo, BPCMs, TS1D3A, TS1D3B, TS1D2A and TS1D2B. They were isolates from South Sumatra. Conidial density of all isolates were significantly decrease if the isolates were incubated at 34 °C. However, only TS1D2B isolate still had high conidial density at incubation temperature of 34 °C. The conidial density decreased at 34 °C due to the lower production of conidia per cm² in agar medium which indicated by hampered colony growth of *B. bassiana* (Fig. 2). The diameter of colony growth reached 90 mm at 25 °C, whereas the diameter of colony growth at 34 °C was only 15-30 mm. Ottati-de-Lima et al. (2014) had stated that *M. anisopliae* could yield optimal colonies in liquid medium from 25 to 30 °C and temperature of 35 °C was detrimental to colony growth of the fungus.

High spore or conidial production of *B. bassiana* occurred at 25-27 °C (Pham, Kim, Kim, & Kim, 2009). The incubation temperature of 34 °C in this research could decrease the conidial density and colony growth of *B. bassiana*.

Viable or germinate conidia was characterized by the following aspects: the change of size and form of conidia compared to size and form of normal conidia (Fig. 3a), conidial wall broke and produced germ tube and followed by elongation of the germ tube (Fig. 3b and 3c). Percentage of conidial germination was used to determine conidial viability. At incubation temperature of 25 °C, the highest value of conidial viability of 24-hour-suspension culture was found on TS1D3A isolate and was not significantly different from other isolates, except BTmKt and BLePd isolates (Table 3). However, the highest value of conidial viability at temperature of

Eka Sumikarsih et al.: *Beauveria bassiana* for *Nilaparvata lugens*.....

34 °C was found on Natural BVR[#] isolate in control of commercial product and was not significantly different from other five isolates consisting of BTmPc, BBY, BtmPe, BTmPd and BTmkbc. Conidial viability of 48-hour-suspension culture at 25 °C for all isolates were high and not significantly different among isolates. Nevertheless, isolates that had the highest conidial viability at 34 °C was Natural BVR[#] isolate and was not significantly different from BTmPc, BBY, BTmPd, TSID3B, TS1D2A and TS1D2B isolates. The temperature increase during

incubation of *B. bassiana* had significant effect on conidial viability (Fig. 4). Conidial viability was significantly decreased if the *B. bassiana* culture was incubated at 34 °C, either for 24-hour-suspension culture (P = 0.00) or 48-hour-suspension culture (P = 0.00). Therefore, incubation temperature at 34 °C for 7 days for *B. bassiana* culture was capable to decrease the fungal conidial germination, although some local isolates of BTmPc, BBY, BTmPd, TSID3B, TS1D2A and TS1D2B could produce high percentage of germination.

Fig. 4. Conidial viability of *Beauveria bassiana* culture incubated for 7 days at 25 and 34 °C in 24-hour (P = 0.00) (a) and 48-hour suspension culture (P = 0.00) (b)

The shape of conidial germination of *B. bassiana* in this research was similar to description of conidial germination given by the following researcher. Conidial germination showed the following signs: broken conidial wall resulting in germ tube formation which had long stretch and increased in size or diameter of conidia (Oliveira, Pauli, Mascarin, & Delalibera, 2015; Safitri, Herlinda, & Setiawan, 2018). Percentage of conidial germination was used to measure conidial viability of the fungus. Conidial viability of *B. bassiana* at

25 °C was high on TS1D3A, BTmKt and BLePd isolates. However, the high conidial viability was found on TS1D3A, commercial BVR#, BTmPc, BBY, BTmPd, TSID3B and TS1D2B isolates at 34 °C. The conidial viability of *B. bassiana* in 24-hour suspension or 48-hour suspension culture was decreased significantly at incubation temperature of 34 °C. The ideal temperature for the conidial germination of *B. bassiana* was in the range of 25 to 27 °C, but *B. bassiana* conidia could still germinate at 32 °C (Constanski et al., 2011). Salim, Md. Rawi,

Eka Sumikarsih et al.: *Beauveria bassiana* for *Nilaparvata lugens*.....

Ahmad, & Al-Shami (2015) had stated that the conidial germination of *B. bassiana* still occurred up to 33 °C. Local isolates of BTmPc, BBY, BTmPd, TS1D3A, TSID3B and TS1D2B originated from soils and insects of South Sumatra and East Java, Indonesia still had high conidial viability at 34 °C. The conidial viability of these local isolates were equivalent to those of the commercial BVR# isolate. The conidial isolates that were capable to germinate at 34 °C were rarely occurred, but only high temperature resistant isolates that had the capability to germinate. According to Salim, Md. Rawi, Ahmad, & Al-Shami (2015) only superior strains of the fungi were able to germinate at above 33 °C. The conidia of the local isolates in this experiment that were capable to germinate at 34 °C had potential to be developed as active ingredients of bioinsecticides to control *N. lugens* in high temperature rice ecosystem, such as wetland or lowland rice ecosystems of South Sumatra, Indonesia. According to Siaga et al. (2019) the temperature occurred in wetland or lowland rice ecosystems of South Sumatra was above 30 °C.

Virulence of *Beauveria bassiana*

The symptom of *N. lugens* nymphs infected by *B. bassiana* started to appear at the second day after being exposed to the fungal conidia with

doses of 1×10^3 conidia per cm^2 . The nymphs had slow movement and finally stopped moving, whereas the healthy nymphs still actively moved on the rice stem. On the third day, some of the sick nymphs were dead and the other infected nymphs which were still alive became unable to move anymore with their legs and stylets attached on the rice stem. On the fourth and fifth days, the dead nymphs hung with their stylets still attached on the rice stem, while all their legs did not grip on the rice stem anymore. On the sixth day, the dead nymphs became hardened and stiff. On the seventh day, their bodies wrinkled, decayed with no smell and their integuments were coated with white color mycelia which gradually became brownish white to dark brown colors (Fig. 5).

Virulence of *B. bassiana* isolates against *N. lugens* nymphs was represented on the percentage of mortality and the lethal time to 50% (LT_{50}) and 95% (LT_{95}) mortality of *N. lugens* nymphs caused by *B. bassiana*. All isolates of *B. bassiana* tested in this experiment were pathogenic against the *N. lugens* nymphs. At temperature of 25 °C, mean mortality of *N. lugens* nymphs with magnitude of 96.67% was found on TS1D2B isolate, whereas the lowest mean mortality with magnitude of 20% was found on BPcPd2 isolate (Table 4).

Remarks: ns = not significantly different; values within a column (the data of each isolate) followed by the same letters were not significantly different at $P < 0.05$ according to HSD test.

The highest value of mean mortality of *N. lugens* nymphs at 34 °C was found on TS1D2B isolate (43.33%), whereas the lowest value of mean mortality of *N. lugens* nymphs was found on Bws Pantura isolate (5%). However, mortality of *N. lugens* nymphs caused by *B. bassiana* was not significantly different among all isolates either at temperature of 25 or 34 °C. The percentage of *N. lugens* mortality was significantly decreased when fungal incubation temperature was increased from 25 to 34 °C ($P = 0.03$) (Fig. 6). Therefore, the

incubation temperature at 34 °C for 7 days was significantly decreased the virulence of some *B. bassiana* isolates.

All isolates of *B. bassiana* were pathogenic against *N. lugens* nymphs. The mortality of the *N. lugens* nymphs caused by all isolates was high. However, virulence of *B. bassiana* isolates against *N. lugens* nymphs was significantly decreased if *B. bassiana* culture was incubated at 34 °C. Virulence of *B. bassiana* was decreased at 34 °C due to the decrease of conidial viability.

Fig. 6. Mortality of *Nilaparvata lugens* caused by *Beauveria bassiana* culture incubated at 25 and 34 °C ($P = 0.003$)

Virulence of *B. bassiana* was affected by the conidial viability (Ghany, 2015). The higher the capability of conidia germinate, the higher the probability of germ tube formation of the conidia penetrate insect cuticle (Butt, Ibrahim, Ball, & Clark, 1994; Fernandes, Rangel, Moraes, Bittencourt, & Roberts, 2007). The local isolates from South Sumatra of BTmPc, BBY, BTmPd, TS1D3A, TS1D3B and TS1D2B in this study still had high conidial viability at 34 °C which in turn cause the high percentage of *N. lugens* mortality. These local isolates could adapt to high temperature of 34 °C and could be chosen as candidates for biocontrol agents of *N. lugens* in wetland or lowland rice ecosystems in Indonesia.

At fungal incubation temperature of 25 °C, mean of LT_{50} values ranged from 2.24 to 5.06 days and the shortest time was found on BTmPd isolate, whereas the longest time was found on 715 HHBanyuwangi isolate (Table 5). Mean of LT_{50} values caused by *B. bassiana* incubated at 34 °C ranged from 2.92 to 10.40 days and the shortest time was found on isolates of BtmMa, BtmSo, BTmSr, BTmkbc, BtmGa, BLePd and TS1D3B. They were isolates from South Sumatra. Whereas, the longest time was found on Bws Pantura isolate. TS1D3B isolate culture incubated at 25 °C had the shortest lethal time values of 2.34 days (LT_{50}) and 7.16 days (LT_{95}). However, LT_{50} values were not significantly different among all isolates of *B. bassiana* and similar trend was also occurred on LT_{95} . Incubation temperature for *B. bassiana* culture affects LT_{50} or LT_{95} values. Mean of LT_{50} or LT_{95} values

was significantly longer on *B. bassiana* incubated at 34 °C than that of *B. bassiana* incubated at 25°C (Fig. 7). Therefore, incubation temperature at 34 °C for 7 days for *B. bassiana* culture could extend the lethal time to 50% and 95% mortality of *N. lugens* nymphs.

The incubation temperature at 34 °C for *B. bassiana* culture could prolong the LT_{50} and LT_{95} of *N. lugens* nymphs, but some isolates that still have short LT_{50} or LT_{95} value were consisted of BtmMa, BtmSo, BTmSr, BTmkbc, BtmGa, BLePd and TS1D3B. LT_{50} or LT_{95} value of *N. lugens* caused by *B. bassiana* was affected by conidial viability of the fungus. The lower percentage of conidial germination caused longer time for the fungus to invade the whole body of insect hosts (Fernandes, Rangel, Moraes, Bittencourt, & Roberts, 2007). In this research, the isolates of BtmMa, BtmSo, BTmSr, BTmkbc, BtmGa, BLePd and TS1D3B at 34°C causing the lethal time to 50% mortality of *N. lugens* nymphs were 3–4 days. The normal time required by conidia to kill insect host was 4–10 days (Ghany, 2015). The time required by *B. bassiana* to kill *N. lugens* nymphs in this study were shorter because the insect hosts were more sensitive than other insect host species. Conidia requires certain time to germinate on insect cuticle surface and subsequently mycelia penetrates into body cavity (Fernandes, Rangel, Moraes, Bittencourt, & Roberts, 2007). Then, the host insect will die whitin 4 days (Butt, Ibrahim, Ball, & Clark, 1994). Next, the fungus yields thousands of new spores on the dead body (Ghany, 2015).

Eka Sumikarsih et al.: *Beauveria bassiana* for *Nilaparvata lugens*.....

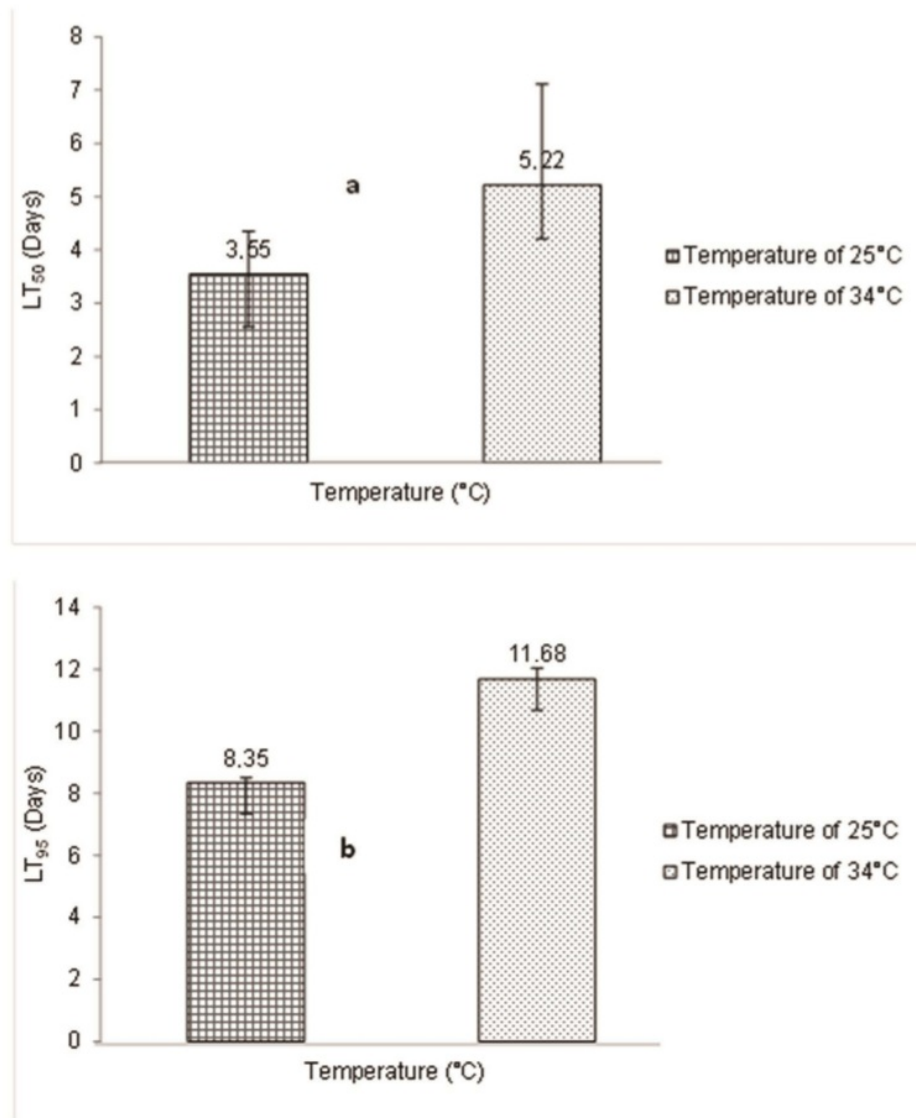

Fig. 7. LT₅₀ ($P = 0.00$) (a) and LT₉₅ ($P = 0.00$) (b) caused by *Beauveria bassiana* culture incubated at 25 and 34 °C against *Nilaparvata lugens*

CONCLUSION

It can be concluded from this study that at germination temperature of 34 °C, some isolates of *B. bassiana* originate from soils or insects, especially from South Sumatra, could produce high conidial density and viability as well as high virulent against *N. lugens* nymphs. The importance of this finding showed that some isolates were still virulent although their culture were incubated at 34 °C for 7 days. Therefore, the isolates can be used as promising candidates for biocontrol for *N. lugens* on rice planted in tropical ecosystem, such as tidal lowland and lowland swamp ecosystems in Indonesia.

ACKNOWLEDGEMENT

This research was supported financially by Program Research Grant Based on Competence (HIKOM) with budget year of 2018 according to the Director of Research and Community Service, Directorate of Research and Community Service (DRPM), Directorate General for Research and Development, Ministry of Research, Technology, and Higher Education, Contract Number: 093/SP2H/LT/DRPM/IV/2018 chaired by Siti Herlinda. Special thanks to Dr. Suwandi for identification of *Beauveria bassiana*.
